Towards A Parallel and Restartable Data Transfer Mechanism in iRODS

Zoey Greer Jason Coposky Terrell Russell Hao Xu

June 5, 2018

Introduction

Current iRODS implementation supports limit parallel transfer and restart capability.

We introduce a design that extends current iRODS to support multiple tasks related to parallel transfer and restart in a unified, general solution.

We want to

- extend rather than completely rewrite the current iCAT.
- put, get, replication symmetrically.
- build API up from microservices.
- support parallel transfer
- support distributed storage of data.
- support partial replicas.
- support automatic restart.
- support partial synchronization.
- support distributed strorage of ICAT efficiently

Data Types

```
type Error
type Range -- = (Int, Bitmap)
type Block
type Data_object -- = (Path, Timestamp)
type Replica -- = (Data_object, Host, Replica_num)
```

Push a block to a resource using block_put. In the following, we use a default block size of 4MB.

・ロト ・ 日 ・ ・ 日 ・ ・ 日 ・ ・ つ へ ()

block_put : (Replica, Range, [Block]) -> ()

This can be used in various operations.

The put operation is initiated by the client by the data_object operation.

▲□▶ ▲圖▶ ▲臣▶ ★臣▶ ―臣 …の�?

data_object : Data_object -> [(Replica, Range)]

This request can be to any server.

For each resource, the client start putting blocks into replicas using the replica operation.

replica : (Replica, Range) -> Range

The returned range is a range of existing blocks on the resource in the input range. Based on returned range, the client sends the blocks to the resource.

(ロ) (型) (E) (E) (E) (O)

Pull a block from a resource using block_get. block_get : (Replica, Range) -> [Block]

put
